

# Reflections on Human Origins

**William A. Dembski**

*version 1.0, 6.21.04*

---

ABSTRACT: The evolutionary literature treats the evolution of humans from ape ancestors as overwhelmingly confirmed. Moreover, this literature defines evolution as an inherently material process without any guidance by an underlying intelligence. This paper reviews the main lines of evidence used to confirm such a materialist view of human evolution and finds them inadequate. Instead, it argues that an evolutionary process unguided by intelligence cannot adequately account for the remarkable intellectual and moral qualities that we see exhibited among humans. The bottom line is that intelligence has played an indispensable role in human origins.

ACKNOWLEDGMENT: I'm grateful to John Bracht for his insights on the similarity between human and chimpanzee DNA and to Russ Howell for sharing with me a working paper that discussed the evolution of mathematical ability.

---

## **1 William James Sidis**

William James Sidis (1898-1944) is by some regarded as the most intellectually gifted person who ever lived. His IQ is estimated to have been between 250 and 300. At eighteen months he could read the *New York Times*. At two he taught himself Latin. At three he learned Greek. At four he was typing letters in French and English. At five he wrote a treatise on anatomy and stunned people with his mathematical ability. At eight he graduated from Brookline High School. He was about to enter Harvard, but the entrance board suggested he take a few years off to develop socially. So he entered Harvard at eleven. At sixteen he graduated cum laude. He became the youngest professor in history. He inferred the possibility of black holes twenty years before Subrahmanyan Chandrasekhar did. As an adult, he could speak more than forty languages and dialects.

Yet the stress of possessing such an amazing intellect took its toll on Sidis. Instead of being appreciated and admired for his intellectual gifts, he was regarded as a freak—an intellectual performer to be stared at rather

than a fellow human being to be cherished. As a teenager at Harvard, he suffered a nervous breakdown. As a professor at Rice University, he was unable to bear the constant media attention. In his early twenties, he resigned his professorship and withdrew from all serious intellectual pursuits. In 1924, a reporter found him working a low-paying job at a Wall Street office. Sidis told the reporter that all he wanted was anonymity and a job that placed no demands on him. Sidis spent the rest of his life working menial jobs.<sup>1</sup>

What does the story of William James Sidis have to do with human origins? A constant theme in the evolutionary literature is that humans are evolved apes and therefore share many key features with apes. Some evolutionists go so far as to claim that human capacities merely extend capacities already incipient in evolutionary ancestors. Darwin himself took this line in *The Descent of Man*. Although important similarities between humans and apes exist, there are also far-reaching differences, most notably differences in intellectual and moral capacities. Extravagant abilities like those of William James Sidis suggest that the difference between humans and other animals is radical and represents a difference in kind and not merely a difference in degree.<sup>2</sup>

## 2 Our Fossil Ancestors?

Why do evolutionists think that humans evolved from apes? Humans are classified as belonging to the genus *Homo* and the species *sapiens*. The genus *Homo* in turn falls within the family *Hominidae*, which includes the apes, and, in particular, the chimpanzees (genus *Pan*). Among extant apes, chimpanzees are thought to be the closest evolutionary cousin of humans. Thus, if humans evolved from apes, their evolution would be entirely at the genus-level. Compare this to the evolution of reptiles into mammals, which represents a class-level transition. If it is plausible to think that reptiles evolved into mammals, which represents a much higher-level transition, then it is even more plausible to think that apes evolved into humans. So reason evolutionists.

Nevertheless, when one examines the actual data and arguments, the case for human evolution becomes less obvious. Take the fossil record. The fossil record contains several extinct species within the genus *Homo*: most recently *Homo neanderthalensis* (the Neanderthals); then *Homo erectus*; and, going even further back, *Homo habilis*. Each of these had

many distinctly human characteristics (for instance, the ability to make tools whose sophistication far exceeds any tools employed by apes). And yet, there is no clear genealogical evidence demonstrating the evolution from *Homo Habilis* to *Homo erectus* to *Homo neanderthalensis* to ourselves, *Homo sapiens*. To be sure, there are similarities. *Homo neanderthalensis* is, by any criterion (anatomical, physiological, cultural) closer to *Homo sapiens* than *Homo erectus*, and the same goes for *Homo erectus* in relation to *Homo habilis*. At best, this shows that *if* humans evolved, then the common ancestor of *Homo sapiens* and *Homo neanderthalensis* is more recent than the common ancestor of *Homo sapiens* and *Homo erectus*, which, in turn, is more recent than the common ancestor of *Homo sapiens* and *Homo habilis*. But such an argument presupposes rather than establishes that humans evolved.

The same problem recurs when we try to argue for human evolution at the genus level. The usual date for the formation of our genus, *Homo*, is about 2.5 million years (*Homo habilis* and *Homo rudolfensis* get the ball rolling). Moreover, the usual date at which the line leading to our genus, *Homo*, is said to have diverged from the line leading to our closest ape cousins, the chimpanzees, is at least 5 million years. In the interim are the *Australopithecines*, which constitute an extinct genus within the *Hominidae*. There's *Australopithecus anamensis* (circa 4 million years ago), *Australopithecus afarensis* (circa 3.5 million years ago), and *Australopithecus africanus* (circa 2.5 million years ago). As before, one can argue on the basis of structural similarity in the fossil record that our common ancestor with *Australopithecus africanus* is more recent than our common ancestor with *Australopithecus afarensis*, which, in turn, is more recent than our common ancestor with *Australopithecus anamensis*. But again, this reasoning is based on the assumption that humans evolved in the first place. Structural similarity, as exhibited in the fossil record, is by itself not enough to establish this. What's needed is independent evidence.

### **3 The Ninety-Eight Percent Chimpanzee?**

The most widely cited evidence for human evolution that is independent of the fossil record is genetic. Human and chimpanzee DNA are 98 percent similar. This fact is taken as decisive confirmation of ape to human evolution. But what does this genetic similarity really mean? Consider, first, that because there are only four nucleotide bases,

whenever one lines up distinct strands of DNA, even entirely random strands will, on average, be 25 percent similar. Consider, further, that chimpanzees (like the other apes) have 48 chromosomes whereas humans have only 46 chromosomes and also that the genome of chimpanzees is about 10 percent larger than that of humans. Thus, if one lined up *all* of human DNA with *all* of chimpanzee DNA, 10 percent of the chimpanzee DNA would have no human counterpart. Looked at in this way, there should be at least a 10 percent difference between human and chimpanzee DNA.

Where, then, does the 98 percent figure come from? In 1984, Charles Sibley and Jon Ahlquist performed a DNA-DNA hybridization experiment in which the DNA of each species was heated in order to separate the individual strands, and the strands from the two species were mixed together and allowed to recombine.<sup>3</sup> The human DNA was allowed to combine with chimp DNA and vice versa. The degree of matching between the strands was measured by heating the human-chimp DNA combination and measuring the temperature at which the strands re-separated. Thus, on thermodynamic grounds, Sibley and Ahlquist found a 1.63 percent difference between the two species, and thus a 98.4 percent identity.

There's a paradox here that parallels the Hox gene paradox: the Hox genes are so similar that in many cases they may be interchanged between extremely divergent species. The paradox, therefore, is how to reconcile the *observed differences* with the *genetic similarity*. There are so many gross morphological similarities between humans and chimpanzees that it's hardly surprising these similarities should be reflected genetically. In the eighteenth century, before evolution was widely accepted, Linnaeus classified the chimpanzee as *Homo troglodytes* ("primitive man"). According to Jonathan Marks, "When the chimpanzee was a novelty in the 18th century, scholars were struck by the overwhelming similarity of human and ape bodies. And why not? Bone for bone, muscle for muscle, organ for organ, the bodies of humans and apes differ only in subtle ways."<sup>4</sup> With so many obvious physical similarities, genetic similarities between humans and chimpanzees are hardly surprising.

Even so, to say that human and chimpanzee DNA are 98 percent similar can be seriously misleading. That's because we tend to think of DNA in terms of written language. There is a crucial difference in the way humans line up parallel texts and molecular biologists line up parallel

strands of DNA. DNA strands form sequences from a four-letter alphabet (usually represented by A, T, C, and G). Likewise, books written by humans form sequences from a twenty-six-letter alphabet. Now, if two books written by humans are 98.4 percent similar, they are essentially the same book. To see this, consider the following sidebar. Here we present Hamlet's famous soliloquy as originally written by Shakespeare. This text is about 1200 characters in length (including spaces and punctuation). Thus, a text at least 98 percent similar to Hamlet's soliloquy will introduce no more than 24 changes. Even if those changes are entirely random, they do not substantially alter the text. To see this, we have modified Hamlet's actual soliloquy by introducing 24 random changes (signified by boldface Xs). Except for one or two words that might be in question, Hamlet's actual soliloquy can be readily recovered from the version with random Xs. That's because written language incorporates redundancy and contextual cues that enable us to determine the words and meaning of a text even when it has been corrupted.

=====BEGIN SIDEBAR=====

Hamlet's Soliloquy:

To be, or not to be: that is the question:  
 Whether 'tis nobler in the mind to suffer  
 The slings and arrows of outrageous fortune,  
 Or to take arms against a sea of troubles,  
 And by opposing end them? To die: to sleep;  
 No more; and by a sleep to say we end  
 The heart-ache and the thousand natural shocks  
 That flesh is heir to, 'tis a consummation  
 Devoutly to be wish'd. To die, to sleep;  
 To sleep: perchance to dream: ay, there's the rub;  
 For in that sleep of death what dreams may come  
 When we have shuffled off this mortal coil,  
 Must give us pause: there's the respect  
 That makes calamity of so long life;  
 For who would bear the whips and scorns of time,  
 The oppressor's wrong, the proud man's contumely,  
 The pangs of despised love, the law's delay,  
 The insolence of office and the spurns  
 That patient merit of the unworthy takes,

When he himself might his quietus make  
 With a bare bodkin? who would fardels bear,  
 To grunt and sweat under a weary life,  
 But that the dread of something after death,  
 The undiscover'd country from whose bourn  
 No traveller returns, puzzles the will  
 And makes us rather bear those ills we have  
 Than fly to others that we know not of?  
 Thus conscience does make cowards of us all;  
 And thus the native hue of resolution  
 Is sicklied o'er with the pale cast of thought,  
 And enterprises of great pith and moment  
 With this regard their currents turn awry,  
 And lose the name of action. - Soft you now!  
 The fair Ophelia! Nymph, in thy orisons  
 Be all my sins remember'd.

98 Percent of Hamlet's Soliloquy (changes marked with bold Xs):

To be, or not to be: that is the question:

=====END SIDEBAR #1=====

The similarity between human and chimpanzee DNA is nothing like the similarity between these two versions of Hamlet's soliloquy. With the two versions of Hamlet's soliloquy, we've lined up the *entire texts* sequentially. By contrast, when molecular biologists line up human and chimpanzee DNA, they are matching *arbitrarily chosen segments* of DNA. It's like going through the works of William Shakespeare and John Milton, and finding that 98 percent of the words and short phrases they used can be lined up letter for letter and therefore are the same. Such a similarity would not be surprising since what separates Shakespeare from Milton is not so much their vocabulary but how they used their vocabulary to express their thoughts. Different authors might use nearly identical sets of words. The crucial difference is in how those words are utilized in their respective contexts. The overall meaning only emerges from the way the words are put together. Hence, even if the same words are used in each, the meanings can be vastly different.

In a similar vein, imagine taking apart a computer, a walkman, and a VCR. Although the function of each device is very different, each contains very similar components. All of these devices incorporate resistors, capacitors, and transistors, and all contain circuit boards and wires. The essential difference is not found at the component level; rather, the essential difference lies in how those components relate to each other in an integrated whole. Likewise, the genes that humans and chimpanzees share are the components that are put together into very different wholes. A 1.63 percent difference in genetics between humans and chimps is able to have

a vastly more than a 1.63 percent difference in effect because the crucial difference resides in the regulatory sequences that control how the genes are used by the organism.

A dramatic study reported in *Science* demonstrates exactly this point. Titled “Intra- and Interspecific Variation in Primate Gene Expression Patterns,” the work by researchers at the Max-Planck-Institute for Evolutionary Anthropology used gene chip technology to measure expression levels of different genes in humans and chimps.<sup>5</sup> They found little difference in genes expressed in blood cells and liver cells of the two species, but when brain cells were compared, massive differences were evident. The difference was so extreme that if humans and chimps are assumed to have shared a common ancestor, humans have accumulated 5.5 times the changes that accumulated in chimps over the same time period. In other words, the rate of change must have been 5.5 times faster in humans than in chimps.

Another aspect of the study utilized a sophisticated 2-dimensional gel electrophoresis technique to separate out proteins from human and chimp brains. Using this technique, the researchers were able to separate out the proteins on the basis of their size and charge. By comparing the data from two species’ brains, two kinds of data can be gathered: qualitative, measuring the differences in types of proteins, and quantitative, measuring the differences in amounts of proteins. The researchers compared the proteins expressed in two mouse species’ brains and found the relative measures were approximately the same: qualitative and quantitative data both showed around a 7 percent difference between the two species. For humans and chimps the researchers also found around a 7 percent qualitative difference; nevertheless, the quantitative difference in this case was over four times higher than expected, namely, 31 percent. This differing pattern of protein quantity reflects the vastly different patterns of gene expression occurring in the neuronal cells of humans versus chimps. This means that even though the genes are remarkably similar, they are being used in very different ways in each species.

The implication, then, is that any explanation of the differences between chimpanzees and humans must describe how their respective gene regulatory networks can be dramatically rewired. There is no such thing as half a gene network; it’s an all-or-nothing affair. After all, by changing one connection between system components (genes), another connection is likely to require a compensating change. Massive,

coordinated changes are needed to reconfigure one gene network into another. The holistic nature of the gene expression system means that minor changes are likely to produce a disconnected mess rather than a coherent, interwoven whole. And it is these vastly different, coherent, interwoven wholes that constitute the gene networks that differ in the brains of humans and chimpanzees.

Ironically, then, the mere 1.63 percent difference between humans and chimps actually makes evolution more tenuous an explanation for that difference. Since the differences are in the network of gene expression, evolution must then be a mechanism capable of re-tooling that network. Re-tooling a gene expression network sounds distinctly like an engineering (teleological) process, not an unguided one. Indeed, we have everyday experience of engineers re-working existing components to make a radically different device. Yet, we have no experience of evolution making such drastic, coordinated changes. Moreover, we have good reason to think that it simply cannot, based on the daunting improbabilities such coordinated changes inevitably require. In other words, when we probe deeper into the details of the 98.4 percent genetic similarity of humans and chimpanzees, we encounter further evidence for design and less for evolution.

#### **4 Language and Intelligence**

Do evolutionists have any other reasons, besides the fossil record and genetic similarity, for thinking that humans evolved from apes? They do, but these other reasons suffer the same defect of overemphasizing similarity and underemphasizing difference. Take, for instance, the capacity of apes for simple symbol manipulation. Apes are capable of acquiring a rudimentary communication system. For instance, Barbara King, a biological anthropologist at the College of William and Mary, describes an ape that developed a taste for champagne and learned to refer to it symbolically.<sup>6</sup> King interprets this capacity as further confirmation of our common ancestry with the apes. But what does this ape really know about champagne other than “that bubbly yellow liquid that tastes good”? Does the ape have any concept of what champagne actually is, namely, an alcoholic beverage made by fermenting grapes, turning it into wine, and then carbonating it? Can the ape acquire this concept as well as the related

concepts needed to understand it? Can the ape deploy this concept in an unlimited number of appropriate contexts, the way humans do? Not at all.

The difficulty confronting evolution is to explain the vast differences between human and ape capacities, not their similarities. Human language is not on a continuum with the communication systems of apes or any other animals. The premier linguist of the 20th century, Noam Chomsky, argued this point at length:

When we study human language, we are approaching what some might call the “human essence,” the distinctive qualities of mind that are, so far as we know, unique to man and that are inseparable from any critical phase of human existence, personal or social.... Having mastered a language, one is able to understand an indefinite number of expressions that are new to one’s experience, that bear no simple physical resemblance and are in no simple way analogous to the expressions that constitute one’s linguistic experience; and one is able, with greater or less facility, to produce such expressions on an appropriate occasion, despite their novelty and independently of detectable stimulus configurations, and to be understood by others who share this still mysterious ability. The normal use of language is, in this sense, a creative activity. This creative aspect of normal language use is one fundamental factor that distinguishes human language from any known system of animal communication.<sup>7</sup>

Chomsky is here responding to a standard move in the evolutionary literature, namely this: evolutionists, upon identifying a similarity between humans and apes (or other animals more generally), use this similarity not to elevate the apes but, rather, to lower the humans. In particular, evolutionists downgrade the feature of our humanity that is the basis for the similarity. We’ve just seen this in the case of human language: because humans and apes both have communication systems, human language is said to be just a more sophisticated (more highly evolved) version of ape communication. Not so. Human language, with its infinite adaptability to different contexts and its ability to create novel concepts and metaphors, has no counterpart in the communication systems of other animals.

In the same way, evolutionists downgrade human intelligence by comparing it with ape and animal intelligence. From the vantage of evolution, intelligence is not a fundamental feature of reality but a product of evolution given to us and other animals because of its survival value. But is that all intelligence is? Might it not be, instead, that intelligence is a fundamental feature of the world, a principle that animates the whole of reality, that is responsible for the marvelous designs we see throughout the

biophysical universe and that is reflected in the cognitive capacities of animals, and preeminently so in humans? The tendency of evolutionists, when they note a similarity between humans and animals, is not to elevate animals by seeing in them a partially developed trait that finds its fulfillment in humans, but to demote humans by dismissing their marvelous gifts as products of evolution that merely extend capacities already present in animal ancestors.

### 5 Morality, Altruism, and Goodness

The most determined move by evolutionists to undercut a human quality that is also reflected in apes concerns our moral sensibilities. Apes, like us, are social creatures. We live in societies structured by moral norms. Those norms facilitate cooperation. They get us to help each other and behave altruistically. Why are we altruistic? According to evolutionary ethics and evolutionary psychology (currently two of the hottest evolutionary subdisciplines), altruism is not a designer's gift to us and the apes; it does not reflect a designer's benevolence. Instead, altruism is a strategy for facilitating survival and reproduction. Altruism, even though it may require sacrificing oneself, nonetheless benefits the survival of the society, and therefore is likely to be favored by evolution. Alternatively, altruism is not really a sacrifice at all but a form of exchange in which one scratches another's back in the expectation that one's own back will, in turn, be scratched. The first of these falls under what is known as *kin selection*, the second under *reciprocal altruism*.

The point to realize is that altruism, the kindness we display toward others at cost to ourselves, is, on evolutionary principles, merely the grease that keeps the evolutionary skids running smoothly. Indeed, evolutionary theorists reinterpret all our moral impulses in this light. Michael Ruse and E. O. Wilson are remarkably straightforward in this regard:

The time has come to take seriously the fact that we humans are modified monkeys, not the favored Creation of a Benevolent God on the Sixth Day. In particular, we must recognize our biological past in trying to understand our interactions with others. We must think again especially about our so-called "ethical principles." The question is not whether biology—specifically, our evolution—is connected with ethics, but how. As evolutionists, we see that no [ethical] justification of the traditional kind is possible. Morality,

or more strictly our belief in morality, is merely an adaptation put in place to further our reproductive ends. Hence the basis of ethics does not lie in God's will.... In an important sense, ethics as we understand it is an illusion fobbed off on us by our genes to get us to cooperate. It is without external grounding. Like Macbeth's dagger, it serves a powerful purpose without existing in substance. Ethics is illusory inasmuch as it persuades us that it has an objective reference. This is the crux of the biological position. Once it is grasped, everything falls into place.<sup>8</sup>

Although this view of morality makes perfect sense within an evolutionary worldview, it quickly disintegrates once one realizes just how slender the evidence for evolution actually is. More significantly for this discussion, however, is that this evolutionary view of morality cannot be squared with the facts of our moral life. Within traditional morality, the main difficulty is to come to terms with the problem of evil. For evolutionary ethics, by contrast, the main difficulty is to come to terms with the problem of good. It is a fact that people perform acts of kindness that cannot be rationalized on evolutionary principles. Altruism is not confined simply to one's in-group (those to whom one is genetically related). Nor is altruism outside one's in-group simply a quid pro quo. People are in fact capable of transcending the self-aggrandizement and grasping for reproductive advantage that evolutionary theorizing regards as lying at the root of ethics.

To see this, consider holocaust rescuers. These were people who aided Jews and others persecuted by the Nazis at great cost and risk to themselves. Jeffrey Schloss writes:

Holocaust rescuers exhibited patterns of aid that uniformly violated selectionist [i.e., evolutionist] expectations. Not only was the risk of death clear and ongoing, but it was not confined to the rescuer. Indeed, the rescuer's family, extended family, and friends were all in jeopardy, and recognized to be in jeopardy by the rescuer. Moreover, even if the family escaped death, they often experienced deprivation of food, space, and social commerce; extreme emotional distress; and forfeiture of the rescuer's attention. What's more, rescuing was unlikely to enhance the reputation of the rescuer: Jews, Gypsies, and other aided individuals were typically despised, and assisting them so violated the laws and prevailing social values that the social consequences included ostracism, forfeiture of possessions, and execution. While it is possible to speculate that reputation and group cohesion within subcultural enclaves could have been enhanced by rescuing, there is little evidence that such enclaves existed, and most rescuers do not testify to belonging to, or knowing of a group that would have

extended support or approval, much less reward or esteem for their actions. Moreover, the overwhelming majority were absolutely secretive about their behavior, not even disclosing it to closest friends or family members outside their immediate dwelling. Finally, the “most unvarying” feature of the behavior and attitudes of all the rescuers was the complete absence of group or individual connections to those aided.<sup>9</sup>

What is the response of evolutionary ethics to people who transcend their selfish genes? Genuine human goodness is an unresolvable problem for evolutionary ethics. Its proponents have only one way of dealing with goodness, namely, to explain it away. Mother Teresa is a prime target in this regard—if Mother Teresa’s acts of goodness on behalf of the poor and sick can be explained away in evolutionary terms, then surely so can all acts of human goodness. For E. O. Wilson, goodness depends on “lying, pretense, and deceit, including self-deceit, because the actor is most convincing who believes that his performance is real.”<sup>10</sup> Accordingly, Wilson attributes Mother Teresa’s acts of goodness to her belief that she will be richly rewarded for them in heaven. In other words, she was simply looking out for number one, acting selfishly in her own self-interest. As Wilson puts it, “Mother Teresa is an extraordinary person but it should not be forgotten that she is secure in the service of Christ and the knowledge of her Church’s immortality.”<sup>11</sup>

And if that explanation doesn’t work, evolutionary ethics can always argue that Mother Teresa’s genetic program misfired, distorting her ethical sensibilities so that she became an evolutionary dead-end, one that evolution would be sure to weed out because it has no use for such extreme do-gooders (as a Catholic nun, Mother Teresa took a vow of celibacy and therefore left no offspring). Thus, instead of treating Mother Teresa as a model of goodness to which we should aspire, evolutionary ethics regards Mother Teresa as a freak of nature with no future. Such rationalizations of human goodness are now standard fare in the evolutionary literature.<sup>12</sup> Certainly, they denigrate our moral sensibilities. More significantly, however, they don’t square with the facts.

## **6 The Benefits of Bigger Brains**

The question therefore remains, how does evolution produce humans with remarkable moral and intellectual capacities like Mother Teresa and William James Sidis? First off, let’s be clear that evolutionists have no

detailed explanations for how such capacities evolved. Indeed, evolutionists never get very far beyond noting that our cognitive capacities require organisms with sizable brains. Take a recent report in *Nature* by Michael Hopkin titled “Jaw-Dropping Theory of Human Evolution: Did Mankind Trade Chewing Power for a Bigger Brain?” According to Hopkin, “Researchers have proposed an answer to the vexing question of how the human brain grew so big. We may owe our superior intelligence to weak jaw muscles, they suggest. A mutation 2.4 million years ago could have left us unable to produce one of the main proteins in primate jaw muscles.... Lacking the constraints of a bulky chewing apparatus, the human skull may have been free to grow, the researchers say.”<sup>13</sup>

Think of what is being argued here. Evolutionists are not simply arguing that a very modest mutation affecting jaw muscles gives brains room to grow. Rather, they are arguing that given room to grow, brains will in fact grow, getting bigger and bigger till—*presto!*—intelligence, language, culture, and amazing people like Mother Teresa and William James Sidis emerge. This isn’t an argument; this is wishful speculation. Indeed, evolutionists never rise above such speculation in accounting for human cognitive capacities. Usually they don’t even get that far. Usually they can’t even identify a concrete biological feature that might be implicated in the distinctly human aspects of cognition. That’s why the jaw-dropping theory of bigger brains aroused so much excitement among evolutionary biologists—here, at least, was an actual genetic mutation that might be implicated in bigger brains and, thus, in human cognition.

Typically, however, evolutionists are content simply to assume that evolution is able to produce bigger brains. And why not? Evolution, after all, is said to have produced everything else of biological significance. Attributing bigger brains to evolution is therefore hardly a stretch. And once bigger brains have evolved, spectacular cognitive abilities are supposed to follow as a matter of course. But how exactly? Unfortunately, evolutionists have no exact answers here. Instead, they propose three types of hypotheses (or combinations of them) to account for the correlation between increased brain size and increased cognitive ability: the adaptationist hypothesis, the byproduct hypothesis, and the sexual-selection hypothesis.

## **7 Explaining Human Mathematical Ability— Three Evolutionary Hypotheses**

Let's consider these hypotheses in turn, but let's do so with respect a specific cognitive ability, namely, mathematics. How did humans acquire their amazing talent for mathematics? According to the adaptationist hypothesis, mathematical ability conferred a clear advantage on our evolutionary ancestors. Those with better mathematical abilities were thus better able to survive and reproduce. In other words, they were better able to "adapt" to their environments (which is the point of calling this an "adaptationist hypothesis"). The adaptationist hypothesis has a certain plausibility when it comes to the acquisition of rudimentary mathematical abilities like simple arithmetic.

Consider, for example, one of our hunter-gatherer ancestors who earlier in the day counted five lions and now sees four of those lions dead from hunting. If he knows basic arithmetic, he can subtract four from five and conclude that one lion is still on the loose. He will thus exercise appropriate caution, which will translate into a survival and reproductive advantage. But rudimentary mathematical abilities are one thing; developing four-dimensional Riemannian geometries that describe a curved spacetime manifold, as Albert Einstein did, is quite another. Here the adaptationist hypothesis breaks down, and other hypotheses are required.

According to the byproduct hypothesis, higher cognitive functions like mathematics are not evolutionary adaptations. Instead, they are unintended byproducts of traits that are adaptive. Spectacular mathematical abilities are thus said to piggyback on the adaptiveness of other capacities. Pascal Boyer offers such an argument. According to him, some rudimentary quantitative ability is adaptive. Boyer then suggests that the capacity to do higher-level mathematics is a byproduct of this rudimentary ability. The higher-level capacity is not adaptive by itself; rather, it emerges as a free rider on abilities that are adaptive. But how, exactly, does rudimentary quantitative ability turn into the ability to develop curved spacetime Riemannian geometries or mathematical theories of comparable sophistication? Boyer doesn't say.<sup>14</sup>

This is always the problem with byproduct hypotheses, namely, bridging the gap between what can be explained in standard evolutionary terms (adaptations) and the unexpected "freebies" (byproducts) that come along for the ride. Some free lunches are just too good to be true. And

precisely when they are too good to be true, they require explanation. That's doubly the case with mathematics: here we have a human capacity that not only emerges, according to the byproduct hypothesis, from other capacities, but also provides fundamental insights into the structure of the physical universe (mathematics is, after all, the language of physics). How could a capacity like that arise as the byproduct of a blind evolutionary process, one unguided by any intelligence? It will not do here simply to say that it could have happened that way. Science does not trade in sheer possibilities. If our mathematical ability is the byproduct of other evolved traits, then the connection with those traits needs to be clearly laid out. To date, it has not.

Finally, we turn to the sexual-selection hypothesis. Sexual selection is Darwin's explanation for how animals acquire traits that have no direct adaptive value. Consider a stag whose antlers are so large that they are more dead-weight than defense. Or consider a peacock whose large colored tail makes it easy prey. Why do such structures evolve? According to Darwin, they evolve because they help to attract mates—they are a form of sexual display. Thus, even though these features constitute a disadvantage for survival in the greater environment, the reproductive advantage they provide in attracting mates more than adequately compensates this disadvantage and provides an evolutionary justification for the formation of these features.

Geoffrey Miller has taken Darwin's idea of sexual selection and applied it to explain the formation of our higher cognitive functions.<sup>15</sup> According to him, extravagant cognitive abilities like those exhibited by mathematical geniuses are essentially a form of sexual display. Once some capacity begins to attract mates, it acts like a positive feedback loop, reinforcing the capacity more and more. In the case of cognitive functions, such a positive feedback loop can run unchecked because there are no environmental constraints to rein it in—unlike stag antlers or peacock tails, which can only get so large before their environmental disadvantage outweighs their ability to attract mates, higher cognitive functions can essentially increase without bound. This, for Miller, is the origin of our higher cognitive functions, and our talent for mathematics in particular.

Leaving aside whether mathematical ability really is a form of sexual display (most mathematicians would be surprised to learn as much), there is a fundamental problem with this and the other two hypotheses we are considering. The problem is not that these hypotheses presuppose

evolution, though that in itself is problematic. The problem, rather, is that each of these three hypotheses fails to provide a detailed, testable model for assessing its validity. If spectacular mathematical ability is adaptive, as the adaptationist hypothesis claims, how do we determine that and what precise evolutionary steps would be needed to achieve that ability? If it is a byproduct of other abilities, as the byproduct hypothesis claims, of which abilities exactly is it a byproduct and how exactly do these other abilities facilitate it? If it is a form of sexual display, as the sexual-selection hypothesis claims, how exactly did this ability mushroom from unspectacular beginnings? The devil is in the details. Certainly, if evolution is true, then one of these hypotheses or some combination of them is likely to account for our ability to do mathematics. But even if evolution is true, apart from a detailed, testable model of how various higher-level cognitive functions emerged, these hypotheses are scientifically sterile.

## 8 The Benefits of Smaller Brains

It will be helpful here, briefly, to return to the issue of brain-size. In the evolutionary literature, all of our spectacular cognitive abilities—mathematical genius, musical genius, poetic genius—presuppose big brains. Regardless of whether those abilities are adaptations, byproducts, or the result of sexual selection, evolutionary theory regards big brains as a necessary evolutionary precursor to these abilities. Now, it's certainly true that big brains are correlated with increasing intelligence. But correlation, as anyone who has taken a course in research methods knows, is not causation. Why, therefore, should we think that big brains are required for the higher cognitive functions?

In fact, there are reliable reports of people exhibiting remarkable cognitive function with very much reduced brain matter. For instance, the December 12, 1980 issue of *Science* contained an article by Roger Lewin titled "Is Your Brain Really Necessary?" In the article, Lewin reported a case study by John Lorber, a British neurologist and professor at Sheffield University:

"There's a young student at this university," says Lorber, "who has an IQ of 126, has gained a first-class honors degree in mathematics, and is socially completely normal. *And yet the boy has virtually no brain.*" The student's physician at the university

noticed that the youth had a slightly larger than normal head, and so referred him to Lorber, simply out of interest. “When we did a brain scan on him,” Lorber recalls, “we saw that instead of the normal 4.5-centimeter thickness of brain tissue between the ventricles and the cortical surface, there was just a thin layer of mantle measuring a millimeter or so. His cranium is filled mainly with cerebrospinal fluid.”<sup>16</sup>

Or consider the case of Louis Pasteur. As Stanley Jaki remarks,

A brain may largely be deteriorated and still function in an outstanding way.... A famous case is that of Pasteur, who at the height of his career suffered a cerebral accident, and yet for many years afterwards did research requiring a high level of abstraction and remained in full possession of everything he learned during his first forty some years. Only the autopsy following his death revealed that he had lived and worked for years with literally one half of his brain, the other half being completely atrophied.<sup>17</sup>

Evolutionists, when confronted with such anomalies, will often remark that the brain contains lots of redundancy. Lorber himself concludes that “there must be a tremendous amount of redundancy or spare capacity in the brain, just as there is with kidney and liver.”<sup>18</sup> But that raises another problem. If much of the brain is redundant, then why didn’t we evolve the same cognitive abilities with smaller brains? Redundancy is all fine and well if there are no hidden costs. But big brains also make it difficult for human babies to pass through the birth canal, which, historically, has resulted in heavy casualties—many mothers and babies have died during delivery. Why should the selective advantage of bigger brains with lots of redundancy outweigh the selective advantage of easier births due to smaller brains that, nonetheless, exercise the same cognitive functions, though without all the redundancy?

There are many deep questions here. The evolutionist may well be right that big brains have an inherent selective advantage. But that has yet to be established. More significantly, it remains an open question how cognitive function relates to neurophysiology. The materialist assumption, entertained by many evolutionists, that mind is reducible to brain remains for now without any empirical support. What we have are correlations between brain images and conscious mental states. What we do not have is a causal mechanism relating the two. Quite the contrary, there are now good reasons for thinking that no such causal mechanism exists and that mind is inherently irreducible to brain.<sup>19</sup>

## 9 Modified Monkey or Modified Dirt?

Where does that leave us with regard to human evolution? In responding to criticisms of evolution on biblical grounds, Thomas Henry Huxley once remarked, “It is as respectable to be modified monkey as modified dirt.”<sup>20</sup> From an intelligent design perspective, the crucial issue is not the respectability of humanity’s physical precursors (monkeys vs. dirt) but what was producing the modifications that brought us about. In particular, is the source behind those modifications intelligent or simply the outworking of blind material forces? Regardless of whether one is a biblical creationist or an atheistic Darwinist or anything in between, all are agreed that humans did not magically materialize out of nothing. Humans arose from preexisting physical stuff. Indeed, the very word “human” refers the dirt (humus) that lies beneath our feet. In this respect, monkeys and humans are both modified dirt, and that is true regardless of whether humans are, in addition, modified monkeys.

Evolution, as the term is typically used, refers to a process of modification that explicitly rules out intelligence. In other words, evolution by intelligent design is not typically what is meant by evolution. Nevertheless, once intelligence is permitted a role in the modifications responsible for humans, it becomes an open question whether humans are both modified monkeys and modified dirt or merely modified dirt. We can ask the same sort of question about an archeological artifact. For instance, is an engraved metal bowl the result of reworking an existing bowl or was it made from scratch by first casting liquid metal in a mold?

There may be good reasons for thinking that humans are redesigned monkeys. Even so, a design-theoretic perspective does not require that novel designs must invariably result from modifying existing designs. Hence, there may also be good reasons for thinking that a redesign process didn’t produce humans and that, instead, humans were built them from the ground up. Design theorists have yet to reach a consensus on these matters. Nevertheless, they have reached a consensus about the indispensability of intelligence in human origins. In particular, they argue that an evolutionary process unguided by intelligence cannot adequately account for the remarkable intellectual gifts of a William James Sidis or the remarkable moral goodness of a Mother Teresa.
